

I got this dataset from Kaggle.com, here is a brief description of the dataset from the source:

PROBLEM STATEMENT

This dataset is crafted for beginners to practice data cleaning and preprocessing techniques in machine learning. It contains **157** rows of student admission records, including duplicate rows, missing values, and some data inconsistencies (e.g., outliers, unrealistic values). It's ideal for practicing common data preparation steps before applying machine learning algorithms.

The dataset simulates a university admission record system, where each student's admission profile includes test scores, high school percentages, and admission status. The data contains realistic flaws often encountered in raw data, offering hands-on experience in data wrangling.

DATASET

The dataset contains the following columns:

Name: Student's first name (Pakistani names). **Age:** Age of the student (some outliers and missing values). **Gender:** Gender (Male/Female). **Admission Test Score:** Score obtained in the admission test (includes outliers and missing values). **High School Percentage:** Student's high school final score percentage (includes outliers and missing values). **City:** City of residence in Pakistan. **Admission Status:** Whether the student was accepted or rejected.

METHODS

Firstly I imported all the necessary libraries I need to carry out the cleaning precisely pandas and the library for visualization matplotlib and seaborn library then I use the `df.info` method to view all the properties of my dataset, then I drop all empty rows, then I remove all outliers afterwards I calculate my acceptance rate, gender ratio and print out the top cities that got admission in the school then finally I use matplotlib and seaborn for the visualization at the end I added a summary that prints the summary of the project and adds it to a file. The model results and the visualization is contained in my notebook attached.
